Section 1. About this tutorial

What does this tutorial cover?

Welcome to "Compiling sources and managing packages," the first of four tutorials designed to prepare you for the Linux Professional Institute's 102 exam. In this tutorial, we'll show you how to compile programs from sources, how to manage shared libraries, and how to use the Red Hat and Debian package management systems.

By the end of this series of tutorials (eight in all), you'll have the knowledge you need to become a Linux Systems Administrator and will be ready to attain an LPIC Level 1 certification from the Linux Professional Institute if you so choose.

The LPI logo is a trademark of Linux Professional Institute.

Should I take this tutorial?

This tutorial on compiling sources and managing packages is ideal for those who want to learn about or improve their Linux package management skills. This tutorial is particularly appropriate for those who will be setting up applications on Linux servers or desktops. For many readers, much of this material will be new, but more experienced Linux users may find this tutorial to be a great way to "round out" their important Linux system administration skills.

If you are new to Linux, we recommend that you first complete the LPI certification 101 exam prep series of tutorials, which includes Part 1: Linux fundamentals, Part 2: Basic administration, Part 3: Intermediate administration, and Part 4: Advanced administration before continuing.

Daniel Robbins lives in Albuquerque, New Mexico, and is the President/CEO of Gentoo Technologies, Inc., the creator of Gentoo Linux, an advanced Linux for the PC, and the Portage system, a next-generation ports system for Linux. He has also served as a contributing author for the Macmillan books Caldera OpenLinux Unleashed, SuSE Linux Unleashed, and Samba Unleashed. Daniel has been involved with computers in some fashion since the second grade, when he was first exposed to the Logo programming language as well as a potentially dangerous dose of Pac Man. This probably explains why he has since served as a Lead Graphic Artist at Sony Electronic Publishing/Psygnosis. Daniel enjoys spending time with his wife, Mary, and their daughter, Hadassah.

Chris Houser, known to many of his friends as "Chouser," has been a UNIX proponent since 1994 when he joined the administration team for the computer science network at Taylor
University in Indiana, where he earned his Bachelor's degree in Computer Science and Mathematics. Since then, he has gone on to work in Web application programming, user interface design, professional video software support, and now Tru64 UNIX device driver programming at Compaq. He has also contributed to various free software projects, most recently to Gentoo Linux. He lives with his wife and two cats in New Hampshire.

Aron Griffis graduated from Taylor University with a degree in Computer Science and an award that proclaimed, “Future Founder of a Utopian UNIX Commune.” Working towards that goal, Aron is employed by Compaq writing network drivers for Tru64 UNIX and spending his spare time plunking out tunes on the piano or developing Gentoo Linux. He lives with his wife, Amy (also a UNIX engineer), in Nashua, New Hampshire.

**Section 2. Shared libraries**

**Introducing shared libraries**

On Linux systems there are two fundamentally different types of Linux executable programs. The first are called *statically linked* executables. Static executables contain all the functions that they need to execute -- in other words, they're “complete.” Because of this, static executables do not depend on any external library to run.

The second are *dynamically linked* executables. We'll get into those in the next panel.

**Static vs. dynamic executables**

We can use the `ldd` command to determine if a particular executable program is static:

```
# ldd /sbin/sln
        not a dynamic executable
```

"not a dynamic executable" is `ldd`'s way of saying that `sln` is statically linked. Now, let's take a look at `sln`'s size in comparison to its non-static cousin, `ln`:

```
# ls -l /bin/ln /sbin/sln
-rwxr-xr-x 1 root root 23000 Jan 14 00:36 /bin/ln
-rwxr-xr-x 1 root root 381072 Jan 14 00:31 /sbin/sln
```

As you can see, `sln` is over ten times the size of `ln`. `ln` is so much smaller than `sln` because it is a dynamic executable. Dynamic executables are *incomplete* programs that depend on external shared libraries to provide many of the functions that they need to run.

**Dynamically linked dependencies**

To view a list of all the shared libraries upon which `ln` depends, use the `ldd` command:

```
# ldd /bin/ln
    libc.so.6 => /lib/libc.so.6 (0x40021000)
    /lib/ld-linux.so.2 => /lib/ld-linux.so.2 (0x40000000)
```

As you can see, `ln` depends on the external shared libraries `libc.so.6` and `ld-linux.so.2`. As a rule, dynamically linked programs are much smaller than their statically-linked equivalents. However, statically-linked programs come in handy for certain low-level maintenance tasks. For example, `sln` is the perfect tool to modify various library symbolic links that exist in `/lib`. But in general, you'll find that nearly all executables on a Linux system are of the dynamically linked variety.

**The dynamic loader**

So, if dynamic executables don't contain everything they need to run, what part of Linux has
the job of loading them along with any necessary shared libraries so that they can execute correctly? The answer is something called the dynamic loader, which is actually the ld-linux.so.2 library that you see listed as a shared library dependency in ln's ldd listing. The dynamic loader takes care of loading the shared libraries that dynamically linked executables need in order to run. Now, let's take a quick look at how the dynamic loader finds the appropriate shared libraries on your system.

### ld.so.conf

The dynamic loader finds shared libraries thanks to two files -- /etc/ld.so.conf and /etc/ld.so.cache. If you cat your /etc/ld.so.conf file, you'll probably see a listing that looks something like this:

```
$ cat /etc/ld.so.conf
```

The ld.so.conf file contains a listing of all directories (besides /lib and /usr/lib, which are automatically included) in which the dynamic loader will look for shared libraries.

### ld.so.cache

But before the dynamic loader can "see" this information, it must be converted into an ld.so.cache file. This is done by running the ldconfig command:

```
# ldconfig
```

When ldconfig completes, you now have an up-to-date /etc/ld.so.cache file that reflects any changes you've made to /etc/ld.so.conf. From this point forward, the dynamic loader will look in any new directories that you specified in /etc/ld.so.conf when looking for shared libraries.

### ldconfig tips

To view all the shared libraries that ldconfig can "see," type:

```
# ldconfig -p | less
```

There's one other handy trick you can use to configure your shared library paths. Sometimes, you'll want to tell the dynamic loader to try to use shared libraries in a specific directory before trying any of your /etc/ld.so.conf paths. This can be handy in situations where you are running an older application that doesn't work with the currently-installed versions of your libraries.

To instruct the dynamic loader to check a certain directory first, set the LD_LIBRARY_PATH variable to the directories that you would like searched. Separate multiple paths using commas; for example:

```
# export LD_LIBRARY_PATH="/usr/lib/old:/opt/lib"
```

After LD_LIBRARY_PATH has been exported, any executables started from the current shell will use libraries in /usr/lib/old or /opt/lib if possible, falling back to the directories specified in /etc/ld.so.conf if some shared library dependencies are still unsatisfied.

We've completed our coverage of Linux shared libraries. To learn more about shared libraries, type man ldconfig and man ld.so.
Section 3. Compiling applications from sources

Introduction

Let's say you find a particular application that you'd like to install on your system. Maybe you need to run a very recent version of this program, but this most recent version isn't yet available in a packaging format such as rpm. Perhaps this particular application is only available in source form, or you need to enable certain features of the program that are not enabled in the rpm by default.

Whatever the reason, whether of necessity or simply just because you want to compile the program from its sources, this section will show you how.

Downloading

Your first step will be to locate and download the sources that you want to compile. They'll probably be in a single archive with a trailing .tar.gz, .tar.Z, .tar.bz2, or .tgz extension. Go ahead and download the archive with your favorite browser or ftp program. If the program happens to have a Web page, this would be a good time to visit it to familiarize yourself with any installation documentation that may be available.

The program you're installing could depend on the existence of any number of other programs that may or may not be currently installed on your system. If you know for sure that your program depends on other programs or libraries that are not currently installed, you'll need to get these packages installed first (either from a binary package like rpm or by compiling them from their sources also.) Then, you'll be in a great position to get your original source file successfully installed.

Unpacking

Unpacking the source archive is relatively easy. If the name of your archive ends with .tar.gz, .tar.Z, or .tgz, you should be able to unpack the archive by typing:

```
$ tar xzvf archivename.tar.gz
```

(x is for extract, z is for gzip decompression, v is for verbose (print the files that are extracted), and f means that the filename will appear next on the command line.)

Nearly all "source tarballs" will create one main directory that contains all the program's sources. This way, when you unpack the archive, your current working directory isn't cluttered with lots of files -- instead, all files are neatly organized in a single directory and don't get in the way.

Listing archives

Every now and then, you may come across an archive that, when decompressed, creates tons of files in your current working directory. While most tarballs aren't created this way, it's been known to happen. If you want to verify that your particular tarball was put together correctly and creates a main directory to hold the sources, you can view its contents by typing:

```
$ tar tvf archivename.tar.gz | more
```

(t is for a text listing of the archive. No extraction occurs.)

If there is no common directory listed on the left-hand side of the archive listing, you'll want to create a new directory, move the tarball inside it, enter the directory, and only then extract the tarball. Otherwise, you'll be in for a mess!

Unpacking bzip2-compressed archives

It's possible that your archive may be in .tar.bz2 format. Archives with this extension have been compressed with bzip2. Bzip2 generally compresses significantly better than gzip. Its only disadvantage is that compression and decompression are slower, and bzip2 consumes more memory than gzip while running. For modern computers, this isn't much of an issue, which is why you can expect bzip2 to become more and more popular as time goes on.

Because bzip2 has been gaining popularity, many Linux distributions come with versions of tar that have been patched with bzip2. Bzip2 generally compresses significantly better than gzip. Its only disadvantage is that compression and decompression are slower, and bzip2 consumes more memory than gzip while running. For modern computers, this isn't much of an issue, which is why you can expect bzip2 to become more and more popular as time goes on.

If neither of these commands work (and tar complains of an invalid argument), there is still hope -- read on.

bzip2 pipelines

So, your version of tar doesn't recognize those handy bzip2 shortcuts -- what can be done? Fortunately, there's an easy way to extract the contents of bzip2 tarballs that will work on nearly all UNIX systems, even if the system in question happens to have a non-GNU version of tar. To view the contents of a bzip2 file, we can create a pipeline:

```
$ cat archive.tar.bz2 | bzip2 -d | tar tvf - | most
```

If you have a patched version of tar, try typing:

```
$ tar tvf archive.tar.bz2 | more
```
or

```
$ tar tivf archive.tar.bz2 | more
```

bzip2 pipelines (continued)

In the previous two examples, we created a standard UNIX pipeline to view and extract files from our archive file. Since tar was called with the v option, it read tar data from stdin,
rather than trying to read data from a file on disk.

If you used the pipeline method to try to extract the contents of your archive and your system complained that bzip2 couldn't be found, it's possible that bzip2 isn't installed on your system. You can download the sources to bzip2 from http://sourceware.cygnus.com/bzip2. After installing the bzip2 sources (by following this tutorial), you'll then be able to unpack and install the application you wanted to install in the first place :)

Inspecting sources

Once you've unpacked your sources, you'll want to enter the unpacked directory and check things out. It's always a good idea to locate any installation-related documentation. Typically, this information can be found in a README or INSTALL file located in the main source directory. Additionally, look for README.platform and INSTALL.platform files, where platform is the name of your particular operating system.

Configuration

Many modern sources contain a configure script in the main source directory. This script (typically generated by the developers using the GNU autoconf program) is specially designed to set up the sources so that they compile perfectly on your system. When run, the configure script probes your system, determining its capabilities, and creates Makefiles, which contain instructions for building and installing the sources on your system.

The configure script is almost always called "configure." If you find a configure script in the main source directory, odds are good that it was put there for your use. If you can't find a configure script, then your sources probably come with a standard Makefile that has been designed to work across a variety of systems -- this means that you can skip the following configuration steps, and resume this tutorial where we start talking about "make."

Using configure

Before running the configure script, it's a good idea to get familiar with it. By typing

```
$ ./configure --help
```

you can view all the various configuration options that are available for your program. Many of the options you see, especially the ones listed at the top of the --help printout, are standard options that will be found in nearly every configure script. The options listed near the end are often related to the particular package you're trying to compile. Take a look at them and note any you'd like to enable or disable.

The --prefix option

Most GNU autoconf-based configure scripts have a --prefix option that allows you to control where your program is installed. By default, most sources install into the /usr/local prefix. This means that binaries end up in /usr/local/bin, man pages in /usr/local/man, etc. This is normally what you want; /usr/local is commonly used to store programs that you compile yourself.

Using --prefix

If you'd like the sources to install somewhere else, say in /usr, you'll want to pass the --prefix=/usr option to configure. Likewise, you could also tell configure to install to your /opt tree, by using the --prefix=/opt option.

What about FHS?

Sometimes, a particular program may default to installing some of its files to non-standard locations on disk. In particular, a source archive may have a number of installation paths that do not follow the Linux Filesystem Hierarchy Standard (FHS). Fortunately, the configure script doesn't just permit the changing of the install prefix, but also allows us to change the install location for various system components such as man pages.

This capability comes in very handy, since most source archives aren't yet FHS-compliant. Nearly always, you'll need to add a --mandir=/usr/share/man and a --infodir=/usr/share/info to the configure command line in order to make your source package FHS-compliant.

Time to configure

Once you've taken a look at the various configure options and determined which ones you'd like to use, it's time to run configure. Please note that you may not need to include any command-line options when you run configure -- in the majority of situations, the defaults will work (but may not be exactly what you want).

Time to configure (continued)

To run configure, type:

```
$ ./configure <options>
```

This could look like:

```
$ ./configure
```

or

```
$ ./configure --prefix=/usr --mandir=/usr/share/man --infodir=/usr/share/info --with-th
```

The options you need will depend on the particular package you're configuring. When you run configure, it will spend a minute or two detecting what particular features or tools are available on your system, printing out the results of its various configuration checks as it goes.

config.cache
Once the configuration process completes, the configure script stores all its configuration data in a file called config.cache. This file lives in the same directory as the configure script itself. If you ever need to run ./configure again after you've updated your system configuration, make sure you rm config.cache first; otherwise, configure will simply use the old settings without rechecking your system.

configure and Makefiles

After the configure script completes, it's time to compile the sources into a running program. A program called make is used to perform this step. If your software package contained a configure script, then when you ran it, configure created Makefiles that were specially customized for your system. These files tell the make program how to build the sources and install the resultant binaries, man pages, and support files.

Makefile intro

Makefiles are typically named makefile or Makefile. There will normally be one makefile in each directory that contains source files, in addition to one that sits in the main source directory. The autoconf-generated Makefiles contain instructions (officially called rules) that specify how to build certain targets, like the program you want to install. make figures out the order in which all the rules should run.

Invoking make

Invoking make is easy; just type "make" in the current directory. The make program will then find and interpret a file called makefile or Makefile in the current directory. If you type "make" all by itself, it will build the default target. Developers normally set up their makefiles so that the default target compiles all the sources:

$ make

Some makefiles won't have a default target, and you'll need to specify one in order to get the compilation started:

$ make all

After typing one of these commands, your computer will spend several minutes compiling your program into object code. Presuming it completes with no errors, you'll be ready to install the compiled program onto your system.

Installation

After the program is compiled, there's one more important step: installation. Although the program is compiled, it's not yet ready for use. All its components need to be copied from the source directory to the correct "live" locations on your filesystem. For example, all binaries need to be copied to /usr/local/bin, and all man pages need to be installed into /usr/local/man, etc.

Before you can install the software, you'll need to become root. This is typically done by either logging in as root on a separate terminal or typing "su," at which point you'll be prompted for root's password. After typing it in, you'll have root privileges until you exit from your current shell session by typing "exit" or hitting control-D. If you're already root, you're ready to go!

make install

Installing sources is easy. In the main source directory, simply type:

$ make install

Typing "make install" will tell make to satisfy the "install" target; this target is traditionally used to copy all the freshly created source files to the correct locations on disk so that your program can be used. If you didn't specify a --prefix option, it's very likely that quite a few files and directories will be copied to your /usr/local tree. Depending on the size of the program, the install target may take anywhere from several seconds to a few minutes to complete.

In addition to simply copying files, make install will also make sure the installed files have the correct ownership and permissions. After make install completes successfully, the program is installed and ready (or almost ready) for use!

Once it's installed

Now that your program is installed, what's next? Running it, of course! If you're not familiar with how to use the program you just installed, you'll want to read the program's man page by typing:

$ man programname

It's possible that a program may require additional configuration steps. For example, if you installed a Web server, you'll need to configure it to start automatically when your system boots. You may also need to customize a configuration file in /etc before your application will run.

Ta da!

Now that you've fully installed a particular software package from its sources, you can now run it! To start the program, type:

$ programname

Congratulations!
Possible problems

It's very possible that configure or make, or possibly even make install, aborted with some kind of error code. The next several panels will help you correct common problems.

Missing libraries

Every now and then, you may experience a problem where configure bombs out because you don't have a certain library installed. In order for you to continue the build process, you'll need to temporarily put your current program configuration on hold and track down the sources or binary package for the library that your program needs. Once the correct library is installed, configure or make should be happy and complete successfully.

Other problems

Sometimes, you'll run into some kind of error that you simply don't know how to fix. As your experience with UNIX/Linux grows, you'll be able to diagnose more and more seemingly cryptic error conditions that you encounter during the configure and make process.

Sometimes, errors occur because an installed library is too old (or possibly even too new!). Other times, the problem you're having is actually the fault of the developers, who may not have anticipated their program running on a system such as yours -- or maybe they just made a typo :)

Other problems (continued)

For problems such as these, use your best judgment to determine where to go for help. If this is your first attempt at compiling a program from source, this may be a good time to select another, easier program to compile. Once you get the simpler program compiled, you may have the necessary experience to fix your originally encountered problem. As you continue to learn more about how UNIX works, you'll get closer to the point where you can actually "tweak" Makefiles and sources to get even seemingly flaky code to compile cleanly.

Section 4. Package management concepts

Package management advantages

Beyond building applications from sources, there's another method for installing software on your Linux system. All Linux distributions employ some form of package management for installing, upgrading, and uninstalling software packages. Package management offers clear advantages over installing directly from source:

- Ease of installation and uninstallation
- Ease of upgrading already-installed packages
- Protection of configuration files
- Simple tracking of installed files

Package management disadvantages

Before jumping into instructions for using the most popular package management tools, I'll acknowledge that there are some Linux users who dislike package management. They might propose some of the following downsides:

- Binaries built for a specific system perform better
- Resolving package dependencies is a headache
- Package database corruption can render a system unmaintainable
- Packages are hard to create

There is some truth to these statements, but the general consensus among Linux users is that the advantages outweigh the disadvantages. Additionally, each stumbling block listed above has a corresponding rebuttal: Multiple packages can be built to optimize for different systems; package managers can be augmented to resolve dependencies automatically; databases can be rebuilt based on other files; and the initial effort expended in creating a package is mitigated by the ease of upgrading or removing that package later.
Section 5. rpm, the (R)ed Hat (P)ackage (M)anager

Getting started with rpm

The introduction of Red Hat's rpm in 1995 was a huge step forward for Linux distributions. Not only did it make possible the management of packages on Red Hat Linux, but due to its GPL license, rpm has become the de facto standard for open source packaging.

The rpm program has a command-line interface by default, although there are GUIs and Web-based tools to provide a friendlier interface. In this section we'll introduce the most common command-line operations, using the Xsnow program for the examples. If you would like to follow along, you can download rpm below, which should work on most rpm-based distributions.

• xsnow-1.41-1.i386.rpm

Note: If you find the various uses of the term "rpm" confusing in this section, keep in mind that "rpm" usually refers to the program, whereas "an rpm" or "the rpm" usually refers to an rpm package.

Installing an rpm

To get started, let's install our Xsnow rpm using rpm -i:

```
# rpm -i xsnow-1.41-1.i386.rpm
```

If this command produced no output, then it worked! You should be able to run Xsnow to enjoy a blizzard on your X desktop. Personally, we prefer to have some visual feedback when we install an rpm, so we like to include the -h (hash marks to indicate progress) and -v (verbose) options:

```
# rpm -ivh xsnow-1.41-1.i386.rpm
```

Re-installing an rpm

If you were following along directly, you might have seen the following message from rpm in the previous example:

```
# rpm -ivh xsnow-1.41-1.i386.rpm
xsnow-1.41-1.i386.rpm is already installed
```

There may be occasions when you wish to re-install an rpm, for instance if you were to accidentally delete the binary /usr/X11R6/bin/xsnow. In that case, you should first remove the rpm with rpm -e, then re-install it. Note that the information message from rpm in the following example does not hinder the removal of the package from the system:

```
# rpm -e xsnow
removal of /usr/X11R6/bin/xsnow failed: No such file or directory
```

Forcibly installing an rpm

Sometimes removing an rpm isn't practical, particularly if there are other programs on the system that depend on it. For example, you might have installed an "x-amusements" rpm which lists Xsnow as a dependency, so using rpm -e to remove Xsnow is disallowed:

```
# rpm -e xsnow
error: removing these packages would break dependencies:
/usr/X11R6/bin/xsnow is needed by x-amusements-1.0-1
```

In that case, you could re-install Xsnow using the --force option:

```
# rpm -ivh --force xsnow-1.41-1.i386.rpm
```

Installing or removing with --nodeps

An alternative to using --force in the previous panel would be to remove the rpm using the --nodeps option. This disables rpm's internal dependency checking, and is not recommended in most circumstances. Nonetheless, it is occasionally useful:

```
# rpm -e --nodeps xsnow
```

```
# rpm -ivh --nodeps xsnow-1.41-1.i386.rpm
```

You can also use --nodeps when installing an rpm. To re-iterate what was said above, using --nodeps is not recommended, however it is sometimes necessary:

```
# rpm -ivh --nodeps xsnow-1.41-1.i386.rpm
```

Upgrading packages

Eventually there will probably be an rpm of Xsnow version 1.42, which is available on the Xsnow author's Website. When that occurs, you'll want to upgrade your existing Xsnow installation. If you were to use rpm -ivh --force, it would appear to work, but rpm's internal database would list both versions as being installed. Instead, you should use rpm -U to upgrade your installation:

```
# rpm -Uvh xsnow-1.42-1.i386.rpm
```

Here's a little trick: we rarely use `rpm -i` at all, because `rpm -U` will simply install an rpm if it doesn't exist yet on the system. This is especially useful if you specify multiple packages on the command-line, where some are currently installed and some are not:

```bash
# rpm -Uvh xsnow-1.42-1.i386.rpm xfishtank-2.1tp-1.i386.rpm
xsnow #####################################xfishtank #####################################
```

Querying with `rpm -q`

You might have noticed in the examples that installing an rpm requires the full filename, but removing an rpm requires only the name. This is because rpm maintains an internal database of the currently installed packages, and you can reference installed packages by name. For example, let's ask rpm what version of Xsnow is installed:

```bash
# rpm -q xsnow
xsnow-1.41-1
```

In fact, rpm knows even more about the installed package than just the name and version. We can ask for a lot more information about the Xsnow rpm using `rpm -qi`:

```bash
# rpm -qi xsnow
Name : xsnow Relocations: (not relocateable)
Release : 1 Build Date: Thu 10 May 2001 01:12:26 AM EDT
Install date: Sat 02 Feb 2002 01:00:43 PM EST Build Host: danx.drydog.com
Group : Amusements/Graphics Source RPM: xsnow-1.41-1.src.rpm
Summary : An X Window System ... his sleigh around the screen on the root window. Xsnow is only for the X Window System, though; consoles just get coal.
```

Listing files with `rpm -ql`

The database maintained by rpm contains quite a lot of information. We've already seen that it keeps track of what versions of packages are installed, and their associated information. It can also list the files owned by a given installed package using `rpm -qi`:

```bash
# rpm -ql xsnow
/etc/X11/applnk/Games/xsnow.desktop
/usr/X11R6/bin/xsnow
/usr/X11R6/man/man1/xsnow.1x.gz
```

Combined with the `-c` option or the `-d` option, you can restrict the output to configuration or documentation files, respectively. This type of query is more useful for larger rpms with long file lists, but we can still demonstrate using the Xsnow rpm:

```bash
# rpm -qlc xsnow
/etc/X11/applnk/Games/xsnow.desktop
# rpm -qld xsnow
/usr/X11R6/man/man1/xsnow.1x.gz
```

Querying all installed packages

You can query all the packages installed on your system by including the `-a` option. If you pipe the output through `sort` and into a pager, then it's a nice way to get a glimpse of what's installed on your system. For example:

```bash
# rpm -qa | sort | less
```

Here's how many rpms we have installed on one of our systems:

```bash
# rpm -qa | wc -l
287
```

And here's how many files are in all those rpms:

```bash
# rpm -qa | wc -l
45706
```

Here's a quick tip: Using `rpm -qa` can ease the administration of multiple systems. If you
redirect the sorted output to a file on one machine, then do the same on the other machine, you can use the `diff` program to see the differences.

Finding the owner for a file

Sometimes it's useful to find out what rpm owns a given file. In theory, you could figure out what rpm owns `/usr/X11R6/bin/xsnow` (pretend you don't remember) using a shell construction like the following:

```
# rpm -qa | while read p; do rpm -ql $p | grep -q '^/usr/X11R6/bin/xsnow$' && echo $p; done
```

Since this takes a long time to type, and even longer to run (1m50s on one of our Pentiums), the rpm developers thoughtfully included the capability in rpm. You can query for the owner of a given file using `rpm -qf`:

```
# rpm -qf /usr/X11R6/bin/xsnow
xsnow-1.41-1
```

Even on the Pentium, that only takes 0.3s to run. And even fast typists will enjoy the simplicity of `rpm -qf` compared to the complex shell construction :)

Showing dependencies

Unless you employ options such as `--nodeps`, rpm normally won't allow you to install or remove packages that break dependencies. For example, you can't install Xsnow without first having the X libraries on your system. Once you have Xsnow installed, you can't remove the X libraries without removing Xsnow first (and probably half of your installed packages).

This is a strength of rpm, even if it's frustrating sometimes. It means that when you install an rpm, it should just work. You shouldn't need to do much extra work, since rpm has already verified that the dependencies exist on the system.

Sometimes when you're working on resolving dependencies, it can be useful to query a package with the `-R` option to learn about everything it expects to be on the system. For example, the Xsnow package depends on the C library, the math library, the X libraries, and specific versions of rpm:

```
# rpm -qR xsnow-1.41-1.1.386.rpm
rpmlib(PayloadFilesHavePrefix) <= 4.0-1
 ld-linux.so.2
 libX11.so.6
 libXext.so.6
 libXpm.so.4
 libX11.so.6
 libXdmcp.so.6(GLIBC_2.0)
 libXdmcp.so.6(GLIBC_2.1.3)
 rpmlib(CompressedFileNames) <= 3.0.4-1
```

Verifying the integrity of a package

When you download an rpm from the Web or an ftp site, for the sake of security you may want to verify its integrity before installing. All rpms are "signed" with an MD5 sum. Additionally, some authors employ a PGP or GPG signature to further secure their packages.

To check the signature of a package, you can use the `--checksig` option:

```
# rpm --checksig xsnow-1.41-1.1.386.rpm
xsnow-1.41-1.1.386.rpm: md5 GPG NOT OK
```

Wait a minute! According to that output, the GPG signature is NOT OK. Let's add some verbosity to see what's wrong:

```
# rpm --checksig -v xsnow-1.41-1.1.386.rpm
xsnow-1.41-1.1.386.rpm:MD5 sum OK: 8ebe63b1dbe86ccd9eaf736a7aa56fd8
gpg: Signature made Thu 10 May 2001 01:16:27 AM EDT using DSA key ID B1F6E46C
gpg: Can't check signature: public key not found
```

So, the problem is that we couldn't retrieve the author's public key. After we retrieve the public key from the package author's Website (shown in the output from `rpm -qi`), the signature checks out:

```
# gpg --import dan.asc
```

```
# rpm --checksig xsnow-1.41-1.1.386.rpm
xsnow-1.41-1.1.386.rpm: md5 gpg OK
```

Verifying an installed package

Similarly to checking the integrity of an rpm, you can also check the integrity of your installed files using `rpm -V`. This step makes sure that the files haven't been modified since they were installed from the rpm:

```
# rpm -V xsnow
```

Normally this command displays no output to indicate a clean bill of health. Let's spice things up and try again:

```
# rm /usr/X11R6/man/man1/xsnow.1.gz
```
Introducing apt-get

The Debian package management system is made up of several different tools. The command-line tool apt-get is the easiest way to install new packages. For example, to install the program Xsnow, do this as the root user:

```
# apt-get install xsnow
```

Reading Package Lists... Done
Building Dependency Tree... Done
The following NEW packages will be installed:
  xsnow
0 packages upgraded, 1 newly installed, 0 to remove and 10 not upgraded.
Need to get 17.8kB of archives. After unpacking 42.0kB will be used.
Get:1 http://ftp-mirror.interact.net stable/non-free xsnow 1.40-6 [17.8kB]
Patched 17.8kB in Os TYPE (18.4KB/s)
Selecting previously deselected package xsnow.
(Reading database ... 5702 files and directories currently installed.)
Unpacking xsnow (from .../archives/xsnow_1.40-6_i386.deb) ...
Setting up xsnow (1.40-6) ...

Simulating install

If apt-get notices that the package you are trying to install depends on other packages, it will automatically fetch and install those as well. In the last example, only Xsnow was installed, because all of it’s dependencies were already satisfied.

Sometimes, however, the list of packages apt-get needs to fetch can be quite large, and it is often useful to see what is going to installed before you let it start. The --dry-run option does exactly this. For example, on one of our systems if we try to install the graphical e-mail program balsa:

```
# apt-get -s install balsa
```

Reading Package Lists... Done
Building Dependency Tree... Done
The following extra packages will be installed:
  esound esound-common gdk-imlib1 gnome-bin gnome-libs-data libart2 libaudiofile libbanshee-base libgnomeui32 libgnorba27 libgnorbagtk libjpeg62 liborbit0 libpng2 libproplist libtiff3g libungif3g zlib1g
The following NEW packages will be installed:
  balsa esound esound-common gdk-imlib1 gnome-bin gnome-libs-data libart2 libaudiofile libbanshee-base libgnomeui32 libgnorba27 libgnorbagtk libjpeg62 liborbit0 libpng2 libproplist libtiff3g libungif3g zlib1g
```

0 packages upgraded, 24 newly installed, 0 to remove and 10 not upgraded.

It then goes on to list the order in which the packages will be installed and configured (or set up).
Package resource list: apt-setup

Since apt-get is automatically fetching packages for you, it must know something about where to find packages that haven't yet been installed. This knowledge is kept in /etc/apt/sources.list. Although you can edit this file by hand (see the sources.list man page), you may find it easier to use an interactive tool:

```
# apt-setup
```

This tool walks you through the process of finding places to get Debian packages, such as CDROMs, Web sites, and ftp sites. When you're done, it writes out changes to your /etc/apt/sources.list file, so that apt-get can find packages when you ask for them.

---

From apt-get to dselect

The apt-get tool has many command-line options that you can read about in the apt-get man page. The defaults usually work fine, but if you find yourself using the same option frequently, you may want to add a setting to your /etc/apt/apt.conf file. This syntax for this configuration file is described in the apt.conf man page.

apt-get also has many other commands besides the install command we've used so far. One of these is apt-get dselect-upgrade, which obeys the Status set for each package on your Debian system.

Starting dselect

The Status for each package is stored in the file /var/lib/dpkg/status, but it is best updated using another interactive tool:

```
# dselect
```

Debian GNU/Linux 'dselect' package handling frontend.

* 0. [A]ccess Choose the access method to use.
1. [U]pdate Update list of available packages, if possible.
2. [S]elect Request which packages you want on your system.
3. [I]nstall Install and upgrade wanted packages.
4. [C]onfig Configure any packages that are unconfigured.
5. [R]emove Remove unwanted software.
6. [Q]uit Quit dselect.

Using dselect Select mode

The Status for each package can be seen under the somewhat cryptic heading EIAM. The column we care about is under the M character, where each package is marked with one of the following:

- Delayed job execution and management of regular back
- Log rotation utility
- Standalone GNU Info document
- Man pages about using a

- 4.4BSD re-implementation

Install and Configure (dpkg-reconfigure)

Debian doesn't install or remove packages based on their Status settings until you run something like apt-get dselect-upgrade. This command actually does several steps for you at once -- Install, Remove, and Configure. The install and remove steps shouldn't need to stop to ask you any questions. The Configure step, however, may ask any number of questions in order to set up the package just the way you want it.

There are other ways to run these steps. For example, you can choose each step individually from the main dselect menu.

Some packages use a system called debconf for their Configure step. Those that do can ask their setup questions in a variety of ways, such as in a text terminal, through a graphical
interface, or through a Web page. To configure one of these packages, use the
dpkg-reconfigure command. You can even use it to make sure all debconf packages
have been completely configured:

```
# dpkg-reconfigure --all
```

debconf: package "3c5x9utils" is not installed or does not use debconf
debconf: package "3dchess" is not installed or does not use debconf
debconf: package "smenu" is not installed or does not use debconf
debconf: package "fmem" is not installed or does not use debconf
debconf: package "azps" is not installed or does not use debconf
debconf: package "azps-perl-j" is not installed or does not use debconf
debconf: package "aalib-bin" is not installed or does not use debconf

This will produce a very long list of packages that do not use debconf, but it will also find
some that do and present easy-to-use forms for you to answer the questions that each
package asks.

### Getting the status of an installed package

The Debian package management tools we've reviewed so far are best for handling
multi-step operations with long lists of packages. But they don't cover some of the
nuts-and-bolts operations of package management. For this kind of work, you want to use
dpkg.

For example, to get the complete status and description of a package, use the
--s option:

```
# dpkg --s xsnow
```

Package: xsnow
Status: install ok installed
Priority: optional
Section: non-free/x11
Installed-Size: 41
Maintainer: Martin Schulze <joey@debian.org>
Version: 1.40-6
Depends: libc6, xlib6g (>= 3.3-5)
Description: Brings Christmas to your desktop

Xsnow is the X-windows application that will let it snow on the
root window, in between and on windows. Santa and his reindeer
will complete your festive-season feeling.

### The link between a file and its .deb

Since a .deb package contains files, you would think there would be a way to list the files
within the package. Well, you would be right; just use the --L option:

```
# dpkg --L xsnow
```

```
/.
/usr
/usr/doc
/usr/doc/xsnow
/usr/doc/xsnow/copyright
/usr/doc/xsnow/readme.gz
/usr/doc/xsnow/changelog.Debian.gz
```

Finding packages to install

Usually, apt-get will already know about any Debian package you might need. If it doesn't,
you may be able to find the package among these lists of Debian packages, or elsewhere on
the Web.

If you do find and download a .deb file, you can install it using the --i option:

```
# dpkg --i /tmp/dl/xsnow_1.40-6_i386.deb
```

If you can't find the package you're looking for as a .deb file, but you find a .rpm or some
other type of package, you may be able to use alien. The alien program can convert
packages from various formats into .debs.

This tutorial was written entirely in XML, using the developerWorks Toot-O-Matic tutorial generator. The open source Toot-O-Matic tool is an XSLT stylesheet and several XSLT extension functions that convert an XML file into a number of HTML pages, a zip file, JPEG heading graphics, and two PDF files. Our ability to generate multiple text and binary formats from a single source file illustrates the power and flexibility of XML. (It also saves our production team a great deal of time and effort.)

You can get the source code for the Toot-O-Matic at www6.software.ibm.com/dl/devworks/dw-tootomatic-p. The tutorial Building tutorials with the Toot-O-Matic demonstrates how to use the Toot-O-Matic to create your own tutorials.
